Chapter 4.2.

PROTISTA

Linda BASSON & Courtney COOK

Protists parasitising freshwater fishes – basic characteristics, life cycles, classification and principal diagnostic features

Protists do not represent a distinct and monophyletic group of organisms. According to Adl *et al.* (2005) Haeckel's taxon Protista (Haeckel 1866) is no longer formally recognised. However, the popular term "protist" is retained to describe eukaryotes with a unicellular level of organisation (eukaryotic microorganisms or EMs; see Chapter 3.3.1). Therefore, this term will be used throughout this chapter, but with no taxonomic validity. The various groups discussed below belong to supergroups as proposed by Adl *et al.* (2012). The only characteristic these organisms share is the fact that they are all unicellular. Very scant information on protist fish parasites in Africa exists.

Each taxonomic group is discussed separately throughout. Host names are presented according to Froese & Pauly (2017). For the purpose of this chapter, the classification system proposed by Adl *et al.* (2012) has been followed. A brief outline of this system is presented in Table 4.2.1, limited to groups of parasites recorded from African freshwater fishes. A generalised key to major groups is presented in Chapter 3.3.1.

In cases where a representative species for every genus could be obtained from the relevant African literature, these species are presented in diagrammatic drawings. However, in several instances only records of genera are provided, with no species identification and/or micrographs or diagrams. In these cases, a representative species from elsewhere in the world was selected and diagrammatically presented.

Chapter 4.3.

MYXOZOA

Ivan FIALA & Pavla BARTOŠOVÁ-SOJKOVÁ

Myxozoa – basic characteristics, life cycles, classification and principal diagnostic features

- parasitic cnidarians (Cnidaria: Myxozoa) with about 2,400 species classified in 67 genera with a worldwide distribution
- endoparasites of fish, annelids and bryozoans, less frequently in amphibians and reptiles; exceptionally in birds, mammals and sipunculids
- two-host life cycle: an invertebrate (annelid or bryozoan) definitive host produces actinospores or malacospores and a vertebrate (mostly fish) intermediate host produces myxospores or fish malacospores (Fig. 4.3.1)
- a vertebrate-derived spore consists mostly of two valves, 1-4 polar capsules and an infectious sporoplasm
- spores microscopic (typically 10-20 µm in size)
- spores develop in vegetative stages (trophozoites, plasmodia) which are histozoic (between tissue cells, e.g., muscles, gills, skin, brain, kidney, liver and spleen) or coelozoic (in cavities, e.g., gall bladder, urinary bladder, lumen of renal tubules and renal corpuscles)
- vegetative stages vary greatly in dimensions, histozoic ones may be macroscopic (up to several cm in diameter)
- trophozoites characterised by cell-within-cell organisation
- species belonging to *Myxobolus* are the most common freshwater myxozoans
- myxozoans from freshwater fishes cluster within the malacosporean clade (*Buddenbrockia*, *Tetracapsuloides*), *Sphaerospora* sensu stricto clade (*Sphaerospora*) and the freshwater (oligochaete) myxosporean lineage (all other genera, e.g., *Myxobolus*).
- causative agents of serious fish diseases, e.g., whirling disease and proliferative kidney disease (PKD)

The classification of the Myxozoa is based on myxospore morphology. The shape of the spore, number of shell valves and polar capsules and the position of the polar capsules within the spore are the most important features for the definition of myxozoan genera (Fiala *et al.* 2015; Fig. 4.3.2). Classification at the species level is based on other spore characteristics such as spore and polar capsule dimensions, spore surface structures, the number of polar filament coils, etc.

The subphylum Myxozoa consists of two classes, the Malacosporea (*Buddenbrockia* and *Tetracapsuloides*) and the Myxosporea with two orders, Bivalvulida and Multivalvulida (mostly marine species, e.g., *Kudoa*). Bivalvulida includes two suborders: Variisporina (e.g., *Myxidium*, *Zschokkella*, *Sphaerospora*, *Hoferellus*, *Chloromyxum* and *Myxobilatus*) and Platysporina (e.g., *Myxobolus*, *Henneguya*, *Thelohanellus* and *Unicauda*) (Fig. 4.3.2).

Chapter 4.4.

MONOGENEA

Eva ŘEHULKOVÁ, Mária SEIFERTOVÁ,
Iva PŘIKRYLOVÁ & Kateřina FRANCOVÁ

Monogenea – basic characteristics, life cycles, classification and principal diagnostic features

- parasitic flatworms with a syncytial tegument (Platyhelminthes: Neodermata)
- over 5,500 species allocated to more than 750 genera
- mostly parasites of freshwater, brackish water and marine fishes; a number of species parasitise crustaceans, cephalopods, amphibians, reptiles and a mammal
- majority of African species found on external surfaces (gills, skin, fins, rarely mouth cavity and nostrils); a few species are endoparasitic (*Enterogyrus* – foregut and stomach, *Urogyrus* – urinary bladder)
- body dorsoventrally flattened, varying in size from ca. 100 µm up to 4 cm long (typically 0.3-10 mm)
- main attachment organ on the posterior end called haptor (or opisthaptor) houses a variable array of sclerotised (hard) structures; number, shape and configuration of the haptor structures are key to species identification and classification
- simple digestive system consisting of mouth, pharynx and intestine with no terminal opening (anus)
- intestine usually with two simple or branched stems often fusing (anastomosing) posteriorly
- hermaphroditic (commonly protandrous), usually with cross-fertilisation
- distal parts of the male and female reproductive system (male copulatory organ, vagina) may contain sclerotised elements (e.g., copulatory tube, accessory piece) that help in species identification
- direct life cycles (no intermediate host required) (Fig. 4.4.1)
- oviparous (oncomiracidium larva), viviparous (sequential polyembryony)
- a high degree of host and site (microhabitat) specificity

The classification of monogeneans is still under discussion. Even the name of the class, Monogenea (used by the majority of workers) or Monogenoidea, is controversial (Wheeler & Chisholm 1995). There are several classifications of monogeneans that are based on morphology, ontogeny and spermatology (Bychowsky 1957; Yamaguti 1963; Lebedev 1988; Malmberg 1990; Justine 1991; Boeger & Kritsky 1993, 2001). The system of Boeger and Kritsky (1993,

Fig. 4.4.1. Life cycles of monogeneans (no intermediate host required). **A.** Oviparous life cycle (*Dactylogyrus* sp.); **B.** Viviparous life cycle (*Macrogyrodactylus* sp.). (Illustrations by M. Luo.)

2001) is followed here for the higher taxonomical levels, based on a variety of anatomical and ultrastructural characters. The subclasses as listed below are now well accepted, as is the division of Heteronchoinea into two infrasubclasses (*i.e.*, Oligonchoinea and Polystomatoinea).

Generic classification of monogeneans is based mainly on characters associated with the attachment structures. However, information on the internal anatomy and sclerotised distal parts of the male and female reproductive system is also important, as an integral part of the generic definition.

Species identification of monogeneans (especially so-called lower monogeneans – Polyonchoinea) is based on the morphology of the sclerotised structures of the haptor and distal parts of the reproductive systems (*i.e.*, male copulatory organ

and vagina). However, details on the arrangement of internal structures may also supplement the taxonomical evaluation, and should ideally be a part of the species description.

The unique and characteristic morphological feature of the Monogenea is the presence of the posterior attachment organ called the haptor (or opisthaptor). It is a complex organ composed of the attachment disc and various sclerotised structures (Fig. 4.4.2). The terminology of the haptoral structures is not unified and some researchers use these terms differently. Here, the following terms are used in keying out these parasites:

Anchors (hamuli, grypi, large hooks, central hooks, Mittelhakens) are paired trifold structures situated on the ventral and/or dorsal surface of the central part of the haptor. One or two pairs of anchors may be present, but in some monogeneans (e.g., species of *Heteronchocleidus*, *Trianchoratus*, *Urogyrus*) one of the anchors may not be fully developed, i.e., it is much reduced in size and shape. In a typical case, the anchor consists of inner root (superficial root, ventral root, guard), outer root (deep root, dorsal root, shaft), base, shaft (blade) and point; the membranous structures arising from the convex surface of the shaft are termed anchor filaments (wings, filament loops). The anchors of some genera may possess accessory sclerites (patch, cuneus) associated with the tip of the inner root (e.g., species of *Birgiellus*, *Paraquadriacanthus*, *Quadriacanthus*).

Bars (connecting bars, transverse bars) are one or two-piece structures connecting the basis of individual members of a pair of anchors. Generally, each pair of anchors has a bar and together they form the so-called ventral and/or dorsal anchor-bar complex. In a number of genera with two pairs of anchors, only one pair has a bar (e.g., species of *Enterogyrus*, *Eutrianchoratus*). Conversely, two bars (ventral and dorsal) may be present in some monogeneans with one pair of anchors (e.g., species of *Dactylogyrus*, *Gyrodactylus*).

Needles (4A hooks) are paired delicate (usually poorly detectable) splinter-like structures of which the nature and origin have not yet been clearly documented. Mostly they are considered to be vestigial anchors or vestigial hooks (e.g., species of *Dactylogyrus*, *Dogielius*, *Schilbetrematoides*).

Hooks (marginal hooks, uncinuli) are bilaterally arranged pairs of small sickle-shaped structures. In a typical case, each hook consists of a sickle (with sickle-filament loop or FH loop) and a handle. There are two types of hooks called unhinged and hinged hooks. The sickle of a hinged hook is movable in relation to the handle. The number of hooks is 14 in species with unhinged hooks (Dactylogyridae, Diplectanidae) and 16 in species with hinged hooks (Gyrodactylidae). There are several types of numbering systems for hook pairs; here the system of Mizelle (1936) is adopted, because it is the only currently used method that considers both the anteroposterior and dorsoventral positions of the respective hook pairs in the adult haptor.

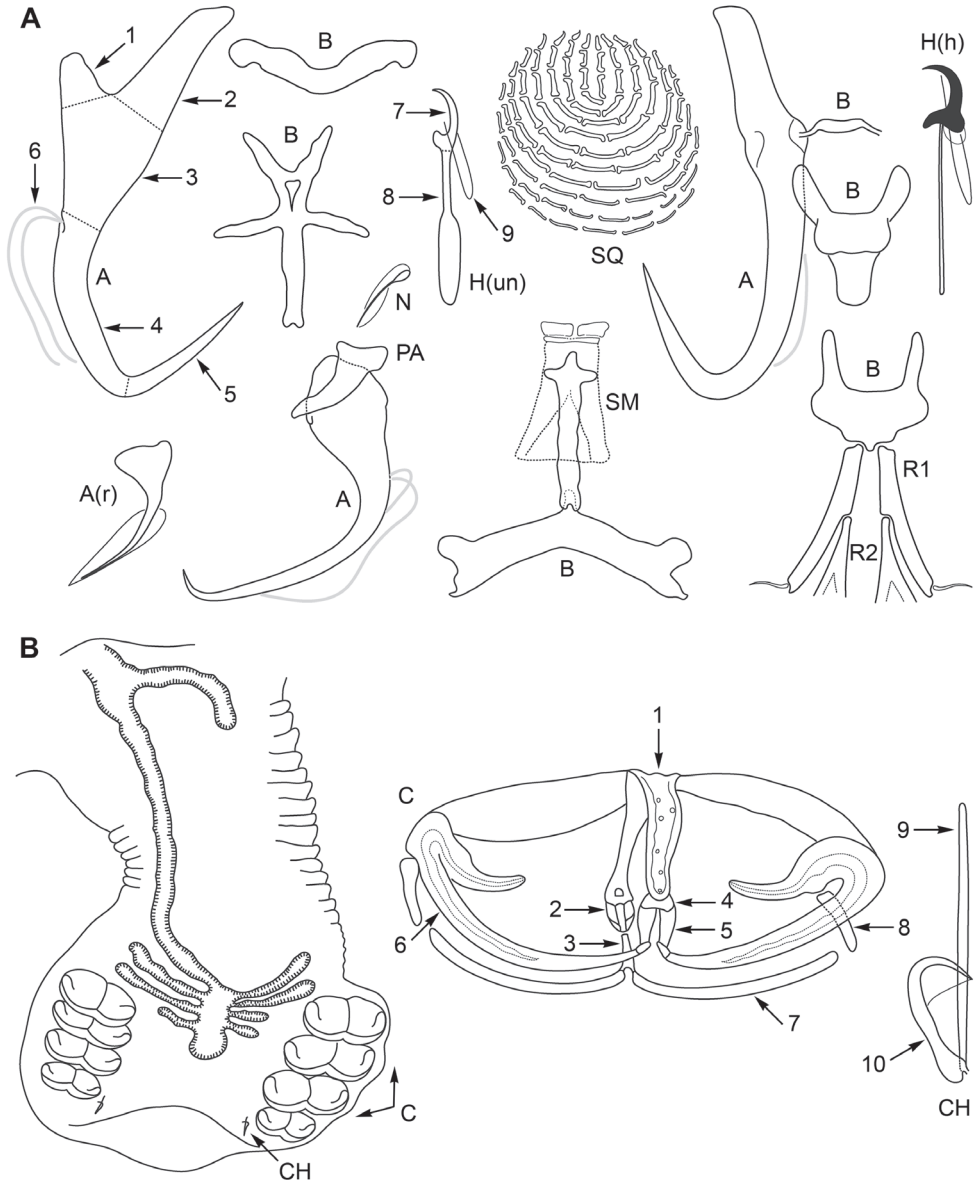

Fig. 4.4.2. Examples of haptoral attachment structures, as typically seen in papers describing new species. **A.** Polyonchoinea. A = anchor, A(r) = anchor (rudimentary), B = bar, H(h) = hook (hinged), H(un) = hook (unhinged), N = needle, Pa = patch, R = rods, SM = supporting membrane, SQ = squamodisc, 1 = outer root, 2 = inner root, 3 = base, 4 = shaft, 5 = point, 6 = filament, 7 = sickle, 8 = handle, 9 = FH loop; **B.** Oligonchoinea. (Modified after Khotenovsky 1985.) C = clamps, CH = central hook, 1 = median plate, 2 = proximal additional sclerite, 3 = distal additional sclerite, 4 = trapeze spur, 5 = anterior joining sclerites, 6 = anterior jaw, 7 = posterior jaw (median sclerite), 8 = posterior jaw (lateral sclerite), 9 = handle, 10 = sickle.

Squamodiscs are circular or oval plate-like formations, which are found only in certain monogeneans of the Diplectanidae. There are, typically, two squamodiscs (one ventral and one dorsal) located anteriorly to the anchor-bar complexes. Each disc possesses scales embedded in the tegument, which appear under the microscope as rootlets arranged in rows.

Clamps are metamorphosed suckers characteristic of higher monogeneans (Oligonchoinea). They are highly specialised structures, often armed with sclerotised elements. The number of clamps varies from two to many; they are distributed symmetrically or asymmetrically. The number and arrangement of clamps as well as the number, shape and size of clamp sclerites are of taxonomic importance in differentiating taxa.

4.4.1. Identification keys for monogeneans (adults)

The guide to the monogeneans parasitising African freshwater fishes is presented here as keys to individual genera and higher-level taxa. Every step in the keys refers to a corresponding figure for a better understanding of identifying feature(s). Figures are labelled to illustrate the used terminology of the sclerotised structures; taxonomically important characters indicated by arrows. In case of hooks, only half of them is depicted in the key to the Dactylogyridae. The genus *Ancyrocephalus* is not included in the keys. Following the emendation of the generic diagnosis for *Ancyrocephalus* of Bychowsky and Nagibina (1970), *A. barilli*, *A. claveaui*, *A. limnotrissae* and *A. pellanulae* do not belong to the genus *sensu stricto*. Nevertheless, we retain them in *Ancyrocephalus* until their generic status is formally resolved. Thus, these species are listed below under *Ancyrocephalus sensu lato*.

4.4.2. A systematic survey of monogeneans on/in African freshwater fishes

Knowledge of monogeneans in Africa is incomplete and the present numbers of these parasites on/in fishes in the region are likely to be an underestimate, as relatively few species of fishes have been examined. Today, more than twenty years since the last compilation (Khalil & Polling 1997), a total of 475 species of polyonchoineans (33 genera in 3 families) and 7 species of oligonchoineans (3 genera in 2 families) have been described. Given the high diversity of freshwater fish species in Africa (more than 3,200 spp.), monogeneans are therefore still poorly known. At the family level, the Dactylogyridae are represented currently by the greatest number of species (423 spp.) belonging to 26 genera: *Afrocleidodiscus* (3), *Ancyrocephalus* (s.l.) (4), *Annulotrema* (48), *Archidiplectanum* (1), *Bagrobdella* (4), *Birgiellus* (3), *Bouixella* (10), *Characidotrema* (10), *Cichlidogyrus* (112), *Dactylogyrus* (100), *Dogiellus* (21), *Enterogyrus* (8), *Eutrianchoratus* (5), *Heteronchocleidus* (5), *Heterotesia* (1), *Insulacleidus* (3), *Nanotrema* (2), *Onchobdella* (8), *Paraquadriacanthus* (1), *Protoancylodiscoides* (9), *Quadriacanthus* (34), *Schilbetrema* (14), *Schilbetrematoides* (2), *Scutogyrus* (7), *Synodontella* (7), and *Urogyrus* (1). Only a single species of diplectanids, *Diplectanum lacustre*, has been reported from *Lates niloticus*. The viviparous gyrodactylids are the second-largest family, with 51 species attributed to 6 genera, *i.e.*, *Afrogyrodactylus* (4), *Citharodactylus* (1), *Diplogyrodactylus* (1), *Gyrodactylus* (35), *Macrogyrodactylus* (9), and *Mormyroggyrodactylus* (1). The only representatives of the Oligonchoinea are 7 species belonging to *Paradiplozoon* (5), *Afrodiplozoon* (1) (Diplozoidae) and one species of *Heterobothrium* (Diclidophoridae).

The catalogue of monogenean species described from freshwater fishes in Africa has been compiled from various sources (*e.g.*, Paperna 1979; Khalil & Polling 1997; Lim *et al.* 2001; Pariselle & Euzet 2009). Mention of the monogenean species in the list does not imply that the authors agree with their validity or taxonomy. Species are listed alphabetically according to individual monogenean genera. The type species of genera and type host of parasite species are highlighted in bold. The country where the type locality lies is also provided if known. Names of hosts recorded here are those provided in FishBase (Froese & Pauly 2017); names used in the original description are retained in square brackets as synonyms.

TREMATODA

Olena KUDLAI, Tomáš SCHOLZ & Nico SMIT

Flukes (Trematoda) – basic characteristics, life cycles, classification and principal diagnostic features

- parasitic flatworms (Platyhelminthes: Neodermata)
- almost 20,000 species classified in 2 subclasses
- subclass Digenea with 2 orders, 25 superfamilies and 148 families
- obligate parasites, almost exclusively endoparasites
- in the digestive system and other organs
- in all groups of vertebrates, with the highest number of species in bony fishes; exceptionally, adults in invertebrates
- body dorsoventrally flattened in most species
- usually with two muscular suckers: the oral sucker at the anterior end of the body and the ventral one (acetabulum) in the mid-region (close to the posterior extremity of the body in Paramphistomatoidea)
- digestive tract well-developed
- body surface covered with tegument (neodermis), sometimes with spines
- all African species in fishes hermaphroditic
- except for some aspidogastreans, life cycles indirect (1-3 intermediate hosts)
- first intermediate hosts molluscs, especially gastropods
- wide spectrum of second intermediate hosts, e.g., molluscs, insects, oligochaetes, fishes
- some species, especially larvae (e.g., metacercariae of the Diplostomidae and Clinostomidae), can be pathogenic for fish hosts
- causative agents of human fish-borne diseases (small liver and intestinal flukes) – not common in Africa

The life cycle of trematodes is complex with both free-living and parasitic stages and involves several hosts (Fig. 4.5.1 A, B). Adults produce eggs that pass in the faeces of the host to the environment where they hatch to release a free-living larva, the miracidium. The miracidium penetrates a molluscan first intermediate host (some marine species infect annelids). After penetration the miracidium develops into a mother sporocyst, the first intramolluscan generation. It multiplies parthenogenetically, producing the second intramolluscan generation – multiple daughter sporocysts or multiple rediae. Daughter sporocysts and rediae reproduce parthenogenetically generating the larvae of the sexual adult – cercariae. There are several ways for cercariae to infect the invertebrate or vertebrate second intermediate host, which host metacercariae. Cercariae may actively penetrate

Fig. 4.5.1. Life cycles of trematodes. **A.** *Diplostomum* sp. (fish serves as the second intermediate host); **B.** *Phyllodistomum* sp. (fish serves as the definitive host). (Illustrations by M. Luo.)

through the skin or be eaten by the host. The vertebrate definitive hosts are infected when they consume the second intermediate host.

Trematoda includes two subclasses, Aspidogastrea and Digenea. The former subclass includes only 61 species (Alves *et al.* 2015) compared with almost 20,000 nominal species of digeneans. The fundamental unit of the **classification** of the Digenea is the superfamily. A total of 25 superfamilies with 148 families have been recognised (see Bray *et al.* 2008). As many as 60 families of digeneans include parasites of fishes, and 38 families are exclusively fish parasites. Relatively few of these families possess unique morphological traits that would differentiate them easily from each other. Therefore, individual families are usually characterised by a unique combination of non-unique morphological characteristics. Life cycles and cercarial morphology also play an important role in family definition. As a result, it is very difficult or almost impossible to present simple keys to the families of fish trematodes in Africa.

Seven basic morphotypes of digeneans are recognised based on their general body plan, especially the number and position of suckers, but most trematodes parasitic in African freshwater fishes belong to the distomatous morphological type, which has two suckers, the oral sucker at the anterior end of the body and the ventral one in the mid-region of the body.

Identification to the genus and species level is based on a high number of morphological characteristics, many of them related to the genital organs, such as relative position of the gonads, their shape and extent, the position of the genital pores, structure of the cirrus-sac, the size of the eggs, etc. (see Gibson *et al.* 2002; Jones *et al.* 2005; Bray *et al.* 2008 for keys to trematode genera).

Systematic survey of flukes (Trematoda) in African freshwater fishes

Trematodes identified at least to the genus level are ordered according to their families, which are listed alphabetically, as are their fish hosts. Identification keys for trematode families and genera are provided in the Keys to the Trematoda (Gibson *et al.* 2002; Jones *et al.* 2005; Bray *et al.* 2008). Type species and type hosts are highlighted in bold. The African country where the type locality lies is given if known. Fish names follow FishBase (Froese & Pauly 2017).

List of metacercariae of flukes (Trematoda) from African freshwater fishes

Note: Due to the simple morphology of larval stages, the existence of morphologically similar species and the lack of knowledge on trematode life cycles, reliable identification of larval stages to the species level is usually impossible based only on morphological characteristics. As a result, some morphology-based identification of metacercariae reported from freshwater fishes in Africa may be misidentifications. Molecular techniques have proven to be efficient for identification and elucidation of the life cycles of parasites and should be applied in future studies.

Chapter 4.6.

CESTODA

Tomáš SCHOLZ & Roman KUČHTA

Tapeworms (Cestoda) – basic characteristics, life cycles, classification and principal diagnostic features

- parasitic flatworms (Platyhelminthes: Neodermata)
- about 5,000 species classified in 19 orders
- obligate endoparasites usually of the digestive system of all groups of vertebrates
- body (strobila) dorsoventrally flattened, usually composed of proglottids (“segments”)
- attachment organs (bothria, bothridia, suckers) on the anterior end called scolex (may be absent)
- digestive tract (intestine) absent
- body surface with hair-like structures called microtriches (absorption of nutrients and attachment)
- all African species hermaphroditic, with well-developed vitellarium (vitelline follicles)
- indirect life cycles (1-2 intermediate hosts: copepods, amphipods, oligochaetes, fishes) [Fig. 4.6.1]
- causative agents of human fish-borne diseases (e.g., broad fish tapeworm) – not in Africa

The classification of cestodes is based on well-defined orders (19 in total at present – Caira & Jensen 2017). They are characterised mainly by the morphology of the scolex (the number and type of attachment organs such as paired bothria and bothridia or four muscular suckers – see Figs 4.6.2B, 4.6.5A) and the morphology of the reproductive organs such as the structure of vitelline follicles (diffuse in the cortex, in lateral bands or compact), position of gonads (in the cortex or medulla), egg morphology, structure of the uterus, etc. (e.g., Fig. 4.6.5B; see Khalil *et al.* 1994 for keys to the orders, families and genera of cestodes, and Caira & Jensen 2017 for updated information on all cestodes).

Generic classification and species identification is based on the size and shape of the scolex and its attachment organs such as suckers and apical organs (it may be muscular, *i.e.*, resembling suckers, or glandular, *i.e.*, comprising gland cells), on proglottid morphology, especially the size, position and shape of gonads (e.g., shape, relative position and size of the terminal genitalia, number of testes, extent of vitelline follicles, shape of the uterus and the number of its lateral diverticula, etc.), size and shape of the eggs, morphology of excretory canals, and many other characteristics.

Key to the orders of tapeworms (Cestoda)

Adults which contain fully developed genital organs and eggs if gravid occur almost exclusively in the intestinal lumen, only *Tetracampus ciliotheca* is also reported to occur in the gall bladder. Larvae called metacestodes, which include plerocercoids and plerocerci, are parenteral, *i.e.*, outside the intestinal lumen except for some tiny larvae of the Gryporhynchidae. Metacestodes do not have fully developed genital organs including eggs and they occur in the mesenteries, intestinal wall, gall bladder and liver.

A systematic survey of tapeworms (Cestoda) in African freshwater fish

Species are listed alphabetically according to individual cestode orders. Keys to individual cestode orders, their families and genera were provided by Khalil *et al.* (1994). Kuchta *et al.* (2008) split the order Pseudophyllidea Van Beneden in Carus, 1863 into the Bothriocephalidea and Diphyllbothriidea; members of both orders parasitise teleost fishes, but those of the latter order only as larvae (plerocercoids). The type species of each genus and the type host of each species are highlighted in bold. The country where the type locality occurs is given if known. Host names are according to Froese & Pauly (2017).

Chapter 4.7.

ACANTHOCEPHALA

Bernd SURES, Yuriy KVACH & Roman KUCHTA

Thorny-headed worms (Acanthocephala) – basic characteristics, life cycles, classification and principal diagnostic features

- parasitic 'worms' (Syndermata: Rotifera)
- about 1,300 species classified in 4 classes (Archiacanthocephala, Eoacanthocephala, Palaeacanthocephala and Polyacanthocephala) and 10 orders (Amin 2013; Warner 2014), from which 19 species occur in Africa
- heteroxenous parasites, with adults in the intestine of vertebrates (definitive hosts) and larvae (cystacanths) in haemocoel of arthropods (intermediate hosts); paratenic hosts (vertebrates) occur occasionally
- behavioural changes of intermediate hosts induced by acanthocephalan larvae (cystacanths) increase their vulnerability to predation and thus foster transmission rates to the definitive host (Sures 2014)
- body divided into a trunk (metasoma) and anterior tip with proboscis armed with hooks (prosoma)

Most of the inner organs of acanthocephalans are located within the trunk. Acanthocephalans are dioecious. The ovaries (ovarian balls) of female worms float in the body cavity. Following fertilisation of mature eggs the ovary degenerates and the body cavity is filled with developing eggs. As soon as eggs contain fully developed first stage larvae (acanthors) they are released by the female through an apparatus called the uterine bell.

In addition to the testes, male worms have one to eight cement glands whose secretions enable a male to plug the vagina of a female after fertilisation. Acanthocephalans lack an intestinal tract and take up all nutrients through their body wall. In addition to nutrients, acanthocephalans take up and accumulate toxic substances such as metals, which makes them excellent indicators of environmental pollution (Sures *et al.* 2017).

Higher-level classification (families, orders and classes – see Amin 2013) is based on the amount of cement glands, the shape of the eggs, presence/absence of subtegumental giant nuclei and spines on the trunk, size and number of proboscis hooks, structure of the excretory system, etc.

At the genus and species-level, the key morphological structure for identification is the proboscis (shape and size of the proboscis, the number of files of proboscis hooks, the number of hooks in individual files, size, shape and type of proboscis hooks, etc.). Other morphological characteristics used for identification include

the size and structure of the egg containing the fully developed acanthor, the position of the cephalic ganglion, the morphology of the reproductive system, e.g., the shape and supination of the penis (male copulatory organ) and the vulva (in females), the number of giant hypodermal nuclei, the length of lemnisci, the size of males and females, etc.

NEMATODA

Šárka MAŠOVÁ & Roman KUČHTA

Nematodes or roundworms (Nematoda) – basic characteristics, life cycles, classification and principal diagnostic features

- roundworms (Ecdysozoa: Nematoda)
- nearly 25,000 species described
- only some groups parasitic in vertebrates
- endoparasites of different organs and tissues
- mostly long narrow cylindrical body, round in cross section, tapered towards both ends
- pseudocoelom
- body surface covered with cuticle
- well-developed digestive tract
- gonochoristic (separate sexes)
- direct or indirect life cycles (Fig. 4.8.1) (monoxeny or heteroxeny)
- four changes of cuticle (moulting)
- causative agents of human fish-borne diseases (*e.g.*, anisakiasis, gnathostomiasis)

Generally, life cycles differ depending upon the species of nematode (Yanong 2002). Development of almost all species of fish nematodes requires an intermediate host with presumable exceptions in some groups such as Capillariidae (see Moravec 2013). A complete nematode life cycle consists of four larval stages (L), separated from one another by a moult (or ecdysis) followed by an immature adult (or subadult): egg → L1 → L2 → L3 → L4 → adult. Larval stages of monoxenous species (with direct life cycle) undergo two transformations after hatching (*e.g.*, Pharyngodonidae). Infective juveniles (L3) may be ingested and mature in the intestine or infect via penetrating the skin and migrate through tissues.

Heteroxenous nematodes (with indirect life cycle) involve one or more intermediate hosts (*e.g.*, *Camallanus* sp. – see Fig. 4.8.1). The first two moults usually occur in the intermediate host. Infection of the definitive host by the L3 is either via ingestion of the intermediate host or inoculation by the intermediate host (Gaugler & Bilgrami 2004).

The classification of nematodes presented here is based on a combination of Moravec (2013), Hodda (2011) and the traditional consensus of nematode relationships according to Blaxter et al. (1998). This presentation includes only parasitic nematode families reported from Africa. Higher-level classification (classes, orders and families) of nematodes is based mainly on the type and morphology of the oesophagus, the anterior part of the digestive tract, the

structure of the anterior end (type of oral opening, lips, interlabia, teeth, buccal cavity, cuticular structures), presence/absence of phasmids, presence and number of caudal papillae, presence/absence of stichosome or trophosome, presence/absence of lateral canals in the excretory system and structure of its terminal duct, type of eggs, morphology of the reproductive system (type of uterus, presence/absence of caudal bursa in males), presence/absence of the precloacal sucker, position of the vulva, etc. (Fig. 4.8.2; see Anderson et al. 2009; Gibbons 2010 for keys up to the genus level).

Generic classification and species identification are based on the details of the anterior end (e.g., deirids, structure of the buccal capsule), the morphology of the male copulatory organs (e.g., spicules, gubernaculum, copulatory bursa), detailed structure of the digestive system (e.g., ventriculus, intestinal caecum, oesophagus, pharynx). Other morphological characteristics used for identification include body size and the proportional size of individual parts (e.g., oesophagus, caeca, tail, position of the vulva) to body length; the position of the excretory pore and the nerve ring, structure of the cuticle; the structures or projections of the eggs and the number and position of caudal papillae. For identification, the infection site and host taxon are also very often important.

Classification of nematodes infecting African fishes

A single asterisk (*) before a nematode's scientific name denotes that the taxon has been recorded only in its larval stage in the given fish host(s). A double asterisk (**) denotes records of both larvae and adults in the given host(s), whilst an unmarked taxon denotes records of only adults in the given host(s).

Chapter 4.9.

CRUSTACEA

Nico SMIT & Kerry HADFIELD

Crustaceans (Crustacea) – basic characteristics, life cycles, classification and principal diagnostic features

- phylum Arthropoda: subphylum Crustacea
- approximately 67,000 species classified in 65 orders (including free-living and parasitic)
- no internal skeleton – only hard chitinous exoskeleton
- old exoskeleton shed by moulting
- two pairs of antennae
- three pairs of mouthparts
- head with two compound eyes
- biramous appendages (split into two)
- gaseous exchange through gills
- abdominal segments with swimming legs (swimmerets)
- tail segment fan-shaped, ending in a telson and uropods
- sexual reproduction (most have separate sexes but some are hermaphrodites)
- several larval stages (including the nauplius larva)
- circulatory system open (no heart, blood does not circulate in blood vessels)
- two part-nervous system with a ventral nerve cord and system of ganglia

The general classification of free-living and parasitic crustaceans is based on well-defined orders (65 at present). In almost every order of the Crustacea there are species in some kind of association with other species. This ranges from facultative to highly specialised parasitism where the parasite undergoes total morphological adaptation, becoming metabolically completely reliant on the host for its survival. In freshwater, crustaceans are mostly associated with fish, but there are a few examples of lernaeid copepods and branchiurans associated with tadpoles and invertebrates.

Life cycles and strategies differ among the different groups of parasitic Crustacea and range from temporary parasites that move between the hosts and substrate (e.g., *Argulus* spp.) and permanently attached parasites (e.g., *Chonopeltis* spp.) that complete their life cycle on the hosts. The number of life stages also differs between groups where, for example, the larvae of species from the copepod genera *Ergasilus* and *Lamproglana* are free swimming and only females become parasitic after a few moults (as copepodites) [Fig. 4.9.1]. All copepod appendages can exhibit sexual dimorphism, but typically this is most commonly found in the

antennulae, maxillipeds and fifth swimming legs. The precise pattern of sexual dimorphism is highly variable and thus the taxonomy of parasitic copepods is based on the adult female in most cases.

The parasitic Crustacea are characterised mainly by the morphology of the body, mouthparts and appendages. Generic classification and species identification is also based on the size and shape of the various appendages and many other characteristics (see below).

A systematic survey of crustaceans (Crustacea) in African freshwater fishes

Keys to genera are provided where applicable. Species are listed alphabetically according to individual crustacean orders. Type species of genera and type host of species are highlighted in bold where available. When no type host is indicated, it means that no type host was originally designated from Africa, and if multiple hosts are indicated it signifies that the original description included more than one host with no specific type host designated. If known, the country where the type locality is situated is also provided. Host names are according to Froese & Pauly (2017) and *Catalog of Fishes* (Eschmeyer *et al.* 2017). Some of the species listed here include those parasitising mullets (Mugilidae) and other fish families that can cross over from marine and brackish regions into the freshwater environment.

List of the Porocephalida from African freshwater fishes

Only larval Porocephalida stages are known to infect fish hosts [Fig. 4.9.5A], however, the morphological information available for the different species on this infective stage is limited. As adults are usually found in the definitive piscivorous vertebrate host (usually a reptile), life-cycle studies or molecular identification may need to be completed for accurate species identification at nymph level.

Chapter 4.10.

HIRUDINEA

Kerry HADFIELD & Nico SMIT

Leeches (Hirudinea) – basic characteristics, life cycles, classification and principal diagnostic features

- phylum Annelida, class Clitellata (segmented worms)
- approximately 680 species globally (480 freshwater)
- cylindrical body
- posterior and anterior disc-shaped suckers
- 34 body segments (constant and do not correspond with the number of rings/annuli observed externally as is seen in other annelids)
- segments divided into rings or annuli (the number of annuli per segment in the middle of the body is taxon-specific)
- number of annuli per segment become progressively reduced towards either end of the body
- each segment with a single, transverse row of sensory structures called sensillae
- no internal skeleton
- often with elaborate colour patterns or brightly coloured
- hermaphrodites
- gaseous exchange through the skin
- eyes and oculiform spots to detect movement
- intermediate hosts for Digenea
- vectors for blood parasites (Haematozoa)

The subclass Hirudinea is divided into two orders based on the morphology of the proboscis and vascular system. Leeches of the order Arhynchobdellida Blanchard, 1894 have a non-protrusible muscular pharynx (with or without jaws) and a haemocoelomic system. Species of the order Rhynchobdellida Blanchard, 1894 have a protrusible proboscis and true vascular system. Sawyer (1986) comprehensively summarised leech biology, behaviour and systematics.

Leeches are hermaphroditic, having separate female and male reproductive systems in one organism. Cross-fertilisation occurs when mating leeches intertwine and spermatozoa are transferred (either by means of a protrusible penis, enclosed in hardened spermatophores, or injected into the body surface of the recipient leech). Internal fertilisation occurs followed by the production of a hardened cocoon (egg case). These cocoons are attached to a solid surface and contain all the eggs as well as a fluid to provide sustenance and energy to the eggs as they grow. Most leeches abandon the cocoons at this stage, but the glossiphoniid leeches show parental care during egg development and after the juveniles have hatched. Once

the juveniles hatch from the cocoons they will seek out a potential host to feed on (Oosthuizen & Siddall 2003).

Leeches are often only temporary ectoparasites and will leave their host shortly after a blood meal. However, some leeches (particularly marine species) may spend most of their lives on a host. In large numbers some leeches can even kill their host (Cruz-Lacierda *et al.* 2000). Leeches can also act as intermediate hosts and vectors for other parasites. Hayes *et al.* (2014) noted a marine fish trypanosome from South Africa, *Trypanosoma nudigobii* Fantham, 1919, inside the marine fish host as well as in the marine leech, *Zeylanicobdella arugamensis* De Silva, 1963. Morphological and molecular techniques were used to confirm the identity of the same trypanosome in both the fish and the leech. The role of a leech as an intermediate host is also known. Recently, *Helobdella adiastrata* Ringuélet, 1972, *Helobdella triserialis* (Blanchard, 1849), *Haementeria eichhorniae* Ringuélet, 1978, and *Haementeria* sp. were noted as secondary intermediate hosts for the digenean, *Australapatemon magnacetabulum* Dubois, 1988, in Argentina (see Davies & Ostrowski de Núñez 2012).

Fig. 4.10.1. Rhynchobdellida. *Batracobdelloides tricarinata* (Blanchard, 1897). **A.** Entire body; **B.** Head region; **C.** Posterior region. (Modified from Oosthuizen 1989.)

A systematic survey of leeches (Hirudinea) in African freshwater fishes

Only a single leech species, *Batracobdelloides tricarinata* (Blanchard, 1897), is currently a confirmed parasite of freshwater fishes from Africa (see Oosthuizen 1989) [Fig. 4.10.1]. However, two other leech species have been mentioned as possible African freshwater fish parasites but without specific hosts or localities recorded. *Hirudo michaelsoni* Augener, 1936 (syn. *Aliolimnatis michaelsoni* Sawyer, 1986) prefers mammalian hosts but according to Oosthuizen & Curtis (1990) also feeds on fishes, amphibians and snails. *Asiaticobdella buntonensis* (Meyer, 1951) (syn. *Limnatis buntonensis* Meyer, 1951) prefers hippopotami but according to Oosthuizen (1991) could possibly feed on freshwater fishes. These two species are excluded from the list of confirmed ectoparasites of African fishes. Fish names are according to Froese & Pauly (2017) and Eschmeyer *et al.* (2017).
